Abstract

We study the a priori semimeasure of sets of P_θ -random infinite sequences, where P_θ is a family of probability distributions depending on a real parameter θ . In the case when for a computable probability distribution P_θ an effectively strictly consistent estimator exists, we show that the Levin's a priori semimeasure of the set of all P_θ -random sequences is positive if and only if the parameter θ is a computable real number. For the Bernoulli family B_θ , we show that the a priori semimeasure of the set $\cup_\theta I_\theta$, where I_θ is the set of all B_θ -random sequences and the union is taken over all non-random θ , is positive.

1. Introduction

We use algorithmic randomness theory to analyze “the size” of sets of infinite sequences random with respect to parametric families of probability distributions.

Let a parametric family of probability distributions P_θ , where θ is a real number, be given such that an effectively strictly consistent estimator exists for this family. The Bernoulli family with a real parameter θ is an example of such family. Theorem 1 shows that the Levin's a priori semimeasure of the set of all P_θ -random sequences is positive if and only if the parameter value θ is a computable real number.

We say that a property of infinite sequences has no “empirical meaning” if the Levin's a priori semimeasure of the set of all sequences possessing this property is 0. In this respect, the model of the biased coin with “a prespecified” probability θ of head is meaningless when θ is a noncomputable real number; noncomputable parameters θ can

¹ This paper was presented in part at 2nd International Computer Science Symposium in Russia. Ekaterinburg, Russia, September 3-7, 2007 [14]. This research was partially supported by Russian foundation for fundamental research: 06-01-00122-a.

have empirical meaning only in their totality, i.e., as elements of some uncountable sets. For example, P_θ -random sequences with noncomputable θ can be generated by a Bayesian mixture of these P_θ using a computable prior. In this case, evidently, the semicomputable semimeasure of the set of all sequences random with respect to this mixture is positive.

We give in Appendix A the simple proof of our previous result (formulated in Theorem 3) which says that the Levin's a priori semimeasure of the set of all infinite binary sequences non-equivalent by Turing to Martin-Löf random sequences is positive. In particular, these sequences are non-random with respect to each computable probability distribution.

We use this result to prove Theorem 4. This theorem shows that a probabilistic machine can be constructed, which with probability close to 1 outputs a random θ -Bernoulli sequence such that the parameter θ is not random with respect to each computable probability distribution. This result can be interpreted such that the Bayesian statistical approach is insufficient to cover all possible "meaningful" cases for θ -random sequences.

2. Preliminaries

Let Ξ be the set of all finite binary sequences, Λ be the empty sequence, and Ω be the set of all infinite binary sequences. We write $x \subseteq y$ if a sequence y is an extension of a sequence x , $l(x)$ is the length of x . For any $\omega \in \Omega$, $\omega^n = \omega_1 \dots \omega_n$. A real-valued function $P(x)$, where $x \in \Xi$, is called semimeasure if

$$\begin{aligned} P(\Lambda) &\leq 1, \\ P(x0) + P(x1) &\leq P(x) \end{aligned} \tag{1}$$

for all x , and the function P is semicomputable from below; this means that the set $\{(r, x) : r < P(x)\}$, where r is a rational number, is recursively enumerable. A definition of upper semicomputability is analogous.

Solomonoff proposed ideas for defining the a priori probability distribution on the basis of the general theory of algorithms. Levin [3,15] gave a precise form of Solomonoff's ideas in a concept of a maximal semimeasure semicomputable from below (see also Li and Vitányi [7], Section 4.5, Shen et al. [10]). Levin proved that there exists a maximal to within a multiplicative positive constant factor semimeasure M semicomputable from below, i.e. such that for every semimeasure P semicomputable from below a positive constant c exists such that the inequality

$$cM(x) \geq P(x) \tag{2}$$

holds for all x . The semimeasure M is called *the a priori* or universal semimeasure.

For any semimeasure Q , its *support set* E_Q is a set of all infinite sequences ω such that $Q(\omega^n) > 0$ for all n , i.e., $E_Q = \bigcup_{Q(x)>0} \Gamma_x$.

A function P is a measure if (1) holds, where both inequality signs \leq are replaced on $=$. Any function P satisfying (1) (with equalities) can be extended on all Borel subsets of Ω if we define $P(\Gamma_x) = P(x)$ in Ω , where $x \in \Xi$ and $\Gamma_x = \{\omega \in \Omega : x \subseteq \omega\}$; after that, we use the standard method for extending P to all Borel subsets of Ω . By simple set in Ω we mean a union of intervals Γ_x from a finite set.

A measure P is computable if it is, at one time, lower and upper semicomputable.

For technical reasons, for any semimeasure P , we consider the maximal measure \bar{P} such that $\bar{P} \leq P$. This measure satisfies

$$\bar{P}(x) = \inf_n \sum_{l(y)=n, x \subseteq y} P(y).$$

In general, the measure \bar{P} is noncomputable (and it is not a probability measure). By (2), for each lower semicomputable semimeasure P , the inequality $c\bar{M}(A) \geq \bar{P}(A)$ holds for every Borel set A , where c is a positive constant.

In the manner of Levin's papers [4–6,15] (see also [13]), we consider combinations of probabilistic and deterministic processes as the most general class of processes for generating data. With any probabilistic process some computable probability distribution can be assigned. Any deterministic process is realized by means of an algorithm. Algorithmic processes transform sequences generated by probabilistic processes into new sequences. More precise, a probabilistic computer is a pair (P, F) , where P is a computable probability distribution, and F is a Turing machine supplied with an additional input tape. In the process of computation this machine reads on this tape a sequence ω distributed according to P and produces a sequence $\omega' = F(\omega)$ (A correct definition see in [4,7,10,13]). So, we can compute the probability

$$Q(x) = P\{\omega \in \Omega : x \subseteq F(\omega)\}$$

that the result $F(\omega)$ of the computation begins with a finite sequence x . It is easy to see that $Q(x)$ is a semimeasure semicomputable from below.

Generally, the semimeasure Q can be not a probability distribution on Ω , since $F(\omega)$ may be finite for some infinite ω .

The converse result is proved in Zvonkin and Levin [15]: for every semimeasure $Q(x)$ semicomputable from below a probabilistic computer (L, F) exists such that

$$Q(x) = L\{\omega | x \subseteq F(\omega)\},$$

for all x , where $L(x) = 2^{-l(x)}$ is the uniform probability distribution on the set of all binary sequences.

Analogously, for any Borel set $A \subseteq \Omega$ consisting of infinite sequences, we consider the probability

$$Q(A) = L\{\alpha \in \Omega : F(\alpha) \in A\} \quad (3)$$

of generating a sequence $\omega \in A$ by means of a probabilistic computer F . Obviously, we have $c\bar{M}(A) \geq Q(A)$ for all such A , where c is a positive constant.

Therefore, by (2) and (3) $M(x)$ and $M(A)$ define universal upper bounds of the probability of generating x and $\omega \in A$ by probabilistic computers.

We distinguish between subsets of Ω of \bar{M} -measure 0 and subsets of positive measure \bar{M} . If $\bar{M}(A) = 0$ then the probability of generating a sequence $\omega \in A$ by means of any probabilistic computer is equal to 0.

The simplest example of a set of \bar{M} -measure 0 is $A = \{\omega\}$, where ω is a non-computable sequence. Indeed, if $\bar{M}\{\omega\} > 0$ then there exist a rational $r > 0$ such that $M(\omega^n) > r$ for all n . Obviously, there are only finite number of uncomparable strings x such that $M(x) > r$. Then there exists an k such that $\omega^k \subseteq x$ and $M(x) > r$ imply $x \subseteq \omega$. We can compute each bit of ω by enumerating all such x .

The sets of \bar{M} -measure 0 were described by Levin [4,6] in terms of quantity of information.

We refer readers to Li and Vitányi [7] and to Shen et al. [10] for the theory of algorithmic randomness. We use definition of a random sequence in terms of universal probability. Let P be some computable measure in Ω . The deficiency of randomness of a sequence $\omega \in \Omega$ with respect to P is defined as

$$d(\omega|P) = \sup_n \frac{M(\omega^n)}{P(\omega^n)}, \quad (4)$$

where $\omega^n = \omega_1\omega_2\ldots\omega_n$. This definition leads to the same class of random sequences as the original Martin-Löf [8] definition. Let R_P be the set of all infinite binary sequences random with respect to a measure P

$$R_P = \{\omega \in \Omega : d(\omega|P) < \infty\}.$$

We also consider *parametric families* of probability distributions $P_\theta(x)$, where θ is a real number; we suppose that $\theta \in [0, 1]$. An example of such family is the Bernoulli family $B_\theta(x) = \theta^k(1 - \theta)^{n-k}$, where n is the length of x and k is the number of ones in it.

We associate with a binary sequence $\theta_1\theta_2\ldots$ a real number with the binary expansion $0.\theta_1\theta_2\ldots$. When the sequence $\theta_1\theta_2\ldots$ is computable or random with respect to some measure we say that the number $0.\theta_1\theta_2\ldots$ is computable or random with respect to the corresponding measure in $[0, 1]$.

We consider probability distributions P_θ computable with respect to a parameter θ . Informally, this means that there exists an algorithm enumerating all triples (x, r_1, r_2) , where $x \in \Xi$ and r_1, r_2 are rational numbers, such that $r_1 < P_\theta(x) < r_2$. This algorithm uses an infinite sequence θ as an additional input; if some triple (x, r_1, r_2) is enumerated by this algorithm then only a finite initial fragment of θ was used in the process of computation (for correct definition, see also Shen et al. [10] and Vovk and V'yugin [11]).

Analogously, we consider parametric lower semicomputable semimeasures. It can be proved that there exist a universal parametric lower semicomputable semimeasure M_θ . This means that for each parametric lower semicomputable semimeasure R_θ there exists a positive constant C such that $CM_\theta(x) \geq R_\theta(x)$ for all x and θ .

The corresponding definition of randomness with respect to a family P_θ is obtained by relativization of (4) with respect to θ

$$d_\theta(\omega) = \sup_n \frac{M_\theta(\omega^n)}{P_\theta(\omega^n)}$$

(see also [3]). This definition leads to the same class of random sequences as the original Martin-Löf [8] definition relativized with respect to a parameter θ .

For any θ , let

$$I_\theta = \{\omega \in \Omega : d_\theta(\omega) < \infty\}$$

be the set of all infinite binary sequences random with respect to the measure P_θ . In case of Bernoulli family, we call elements of this set *θ -Bernoulli sequences*.

3. Randomness with respect to a parameter family

We need some statistical notions (see Cox and Hinkley [2]). Let P_θ be some computable parametric family of probability distributions. A function $\hat{\theta}(x)$ from Ξ to $[0, 1]$ is called *an estimator*. An estimator $\hat{\theta}$ is called *strictly consistent* if for each parameter value θ for P_θ -almost all ω ,

$$\hat{\theta}(\omega^n) \rightarrow \theta$$

as $n \rightarrow \infty$.

Let ϵ and δ be rational numbers. An estimator $\hat{\theta}$ is called *effectively strictly consistent* if there exists a computable function $N(\epsilon, \delta)$ such that for each θ for all ϵ and δ

$$P_\theta\{\omega \in \Omega : \sup_{n \geq N(\epsilon, \delta)} |\hat{\theta}(\omega^n) - \theta| > \epsilon\} \leq \delta \quad (5)$$

The strong law of large numbers Borovkov [1] (Chapter 5)

$$B_\theta \left\{ \sup_{k \geq n} \left| \frac{1}{k} \sum_{i=1}^k \omega_i - \theta \right| \geq \epsilon \right\} < \frac{1}{\epsilon^4 n}$$

shows that the function $\hat{\theta}(\omega^n) = \frac{1}{n} \sum_{i=1}^n \omega_i$ is a computable strictly consistent estimator for the Bernoulli family B_θ .

Proposition 1 *For any effectively strictly consistent estimator $\hat{\theta}$,*

$$\lim_{n \rightarrow \infty} \hat{\theta}(\omega^n) = \theta$$

for each $\omega \in I_\theta$.

Proof. Assume an infinite sequence ω be Martin-Löf random with respect to P_θ for some θ .

At first, we prove that $\lim_{n \rightarrow \infty} \hat{\theta}(\omega^n)$ exists. Let for $j = 1, 2, \dots$,

$$W_j = \{\alpha \in \Omega : (\exists n, k \geq N(1/j, 2^{-(j+1)})) |\hat{\theta}(\alpha^n) - \hat{\theta}(\alpha^k)| > 1/j\}.$$

By (5) for any θ , $P_\theta(W_j) < 2^{-j}$ for all j . Define $V_i = \cup_{j > i} W_j$ for all i . By definition for any θ , $P_\theta(V_i) < 2^{-i}$ for all i . Also, any set V_i can be represented as a recursively enumerable union of intervals of type Γ_x . To reduce this definition of Martin-Löf test to the definition of the test (4) define a sequence of uniform lower semicomputable parametric semimeasures

$$R_{\theta,i}(x) = \begin{cases} 2^i P_\theta(x) & \text{if } \Gamma_x \subseteq V_i \\ 0 & \text{otherwise} \end{cases}$$

and consider the mixture $R_\theta(x) = \sum_{i=1}^{\infty} \frac{1}{i(i+1)} R_{\theta,i}(x)$.

Suppose that $\lim_{n \rightarrow \infty} \hat{\theta}(\omega^n)$ does not exist. Then for each sufficiently large j , $|\hat{\theta}(\omega^n) - \hat{\theta}(\omega^k)| > 1/j$ for infinitely many n and k . This implies that $\omega \in V_i$ for all i , and then for some positive constant c ,

$$d_\theta(\omega) = \sup_n \frac{M_\theta(\omega^n)}{P_\theta(\omega^n)} \geq \sup_n \frac{R_\theta(\omega^n)}{c P_\theta(\omega^n)} = \infty,$$

i.e., ω is not Martin-Löf random with respect to P_θ .

Suppose that $\lim_{n \rightarrow \infty} \hat{\theta}(\omega^n) \neq \theta$. Then the rational numbers r_1, r_2 exist such that $r_1 < \lim_{n \rightarrow \infty} \hat{\theta}(\omega^n) < r_2$ and $\theta \notin [r_1, r_2]$. Since the estimator $\hat{\theta}$ is consistent, $P_\theta\{\alpha : r_1 < \lim_{n \rightarrow \infty} \hat{\theta}(\alpha^n) < r_2\} = 0$, and we can effectively (using θ) enumerate an infinite sequence of positive integer numbers $n_1 < n_2 < \dots$ such that for

$$W'_j = \cup\{\Gamma_x : l(x) \geq n_j, r_1 < \hat{\theta}(x) < r_2\},$$

we have $P_\theta(W'_j) < 2^{-j}$ for all j . Define $V'_i = \cup_{j > i} W'_j$ for all i . We have $P_\theta(V'_i) \leq 2^{-i}$ and $\omega \in V'_i$ for all i . Then ω can not be Martin-Löf random with respect to P_θ . These two contradictions obtained above prove the proposition. \triangle

The following theorem generalizes the simplest example of a set of \bar{M} -measure 0 presented in Section 2. It can be interpreted such that P_θ -random sequences with “a prespecified” noncomputable parameter θ can not be obtained in any combinations of stochastic and deterministic processes.

Theorem 1 *Assume a computable parametric family P_θ of probability distributions has an effectively strictly consistent estimator. Then for each θ , $\bar{M}(I_\theta) > 0$ if and only if θ is computable.*

Proof. If θ is computable then the probability distribution P_θ is also computable and by (2) $c\bar{M}(I_\theta) \geq P_\theta(I_\theta) = 1$, where c is a positive constant.

The proof of the converse assertion is more complicated. Assume $\bar{M}(I_\theta) > 0$. There exists a simple set V (a union of a finite set of intervals) and a rational number r such that $\frac{1}{2}\bar{M}(V) < r < \bar{M}(I_\theta \cup V)$. For any finite set $X \subseteq \Xi$, let $\bar{X} = \cup_{x \in X} \Gamma_x$.

Let n be a positive integer number. When we compute a rational approximation θ_n of θ up to $\frac{1}{2n}$ as follows. Using the exhaustive search, we find a finite set X_n of pairwise incomparable finite sequences of length $\geq N(1/n, 2^{-n})$ such that

$$\begin{aligned} \bar{X}_n &\subseteq V, \quad \sum_{x \in X_n} M(x) > r, \\ |\hat{\theta}(x) - \hat{\theta}(x')| &\leq \frac{1}{2n} \end{aligned} \tag{6}$$

for all $x, x' \in X_n$. If any such set X_n will be found, we put $\theta_n = \hat{\theta}(x)$, where x is the minimal element of X_n with respect to some natural (lexicographic) ordering of all finite binary sequences.

Let us prove that for each n some such set X_n exists. Since $\bar{M}(I_\theta \cap V) > r$, there exists a closed (in the topology defined by intervals Γ_x) set $E \subseteq I_\theta \cap V$ such that $\bar{M}(E) > r$. Consider the function

$$f_k(\omega) = \inf\{n : n \geq k, |\hat{\theta}(\omega^n) - \theta| \leq \frac{1}{4n}\}.$$

By Proposition 1 this function is continuous on Ω and, since the set E is compact, it is bounded on E . Hence, for each k , there exists a finite set $X \subseteq \Xi$ consisting of pairwise incomparable sequences of length $\geq k$ such that $E \subseteq \bar{X}$ and $|\hat{\theta}(x) - \hat{\theta}(x')| \leq \frac{1}{2n}$ for all $x, x' \in X$. Since $E \subseteq \bar{X}$, we have $\sum_{x \in X} M(x) > r$. Therefore, the set X_n can be found by exhaustive search.

Lemma 1 *For any Borel set $V \subseteq \Omega$, $\bar{M}(V) > 0$ and $V \subseteq I_\theta$ imply $P_\theta(V) > 0$.*

Proof. By definition of M_θ each computable parametric measure P_θ is absolutely continuous with respect to the measure \bar{M}_θ , and so, we have representation

$$P_\theta(X) = \int_X \frac{dP_\theta}{d\bar{M}_\theta}(\omega) d\bar{M}_\theta(\omega), \quad (7)$$

where $\frac{dP_\theta}{d\bar{M}_\theta}(\omega)$ is the Radon-Nicodim derivative; it exists for \bar{M}_θ -almost all ω .

By definition we have for \bar{M}_θ -almost all $\omega \in I_\theta$

$$\frac{dP_\theta}{d\bar{M}_\theta}(\omega) = \lim_{n \rightarrow \infty} \frac{P_\theta}{\bar{M}_\theta}(\omega^n) \geq \liminf_{n \rightarrow \infty} \frac{P_\theta}{\bar{M}_\theta}(\omega^n) \geq C_{\theta, \omega} > 0. \quad (8)$$

By definition $c_\theta \bar{M}_\theta(X) \geq \bar{M}(X)$ for all Borel sets X , where c_θ is some positive constant (depending on θ). Then by (7) and (8) the inequality $\bar{M}(X) > 0$ implies $P_\theta(X) > 0$ for each Borel set X . \triangle

We rewrite (5) in the form

$$E_n = \{\omega \in \Omega : \sup_{N \geq N(1/(2n), 2^{-n})} |\hat{\theta}(\omega^N) - \theta| \geq \frac{1}{2n}\}. \quad (9)$$

By definition $P_\theta(E_n) \leq 2^{-n}$ for all n . We prove that $X_n \not\subseteq E_n$ for almost all n . Suppose that the opposite assertion holds. Then there exists an increasing infinite sequence of positive integer numbers n_1, n_2, \dots such that $X_{n_i} \subseteq E_{n_i}$ for all $i = 1, 2, \dots$. This implies $P_\theta(X_{n_i}) \leq 2^{-n_i}$ for all i . For any k , define $U_k = \cup_{i \geq k} X_{n_i}$. Clearly, we have for all k , $\bar{M}(\bar{U}_k) > r$ and $P_\theta(\bar{U}_k) \leq \sum_{i \geq k} 2^{-n_i} \leq 2^{-n_k+1}$. Let $U = \cap U_k$. Then $P_\theta(U) = 0$ and

$\bar{M}(U) \geq r > \frac{1}{2} \bar{M}(V)$. From $U \subseteq V$ and $\bar{M}(I_\theta \cap V) > \frac{1}{2} \bar{M}(V)$ the inequality $\bar{M}(I_\theta \cap U) > 0$ follows. Then the set $I_\theta \cap U$ consists of P_θ -random sequences, $P_\theta(I_\theta \cap U) = 0$ and $\bar{M}(I_\theta \cap U) > 0$. This is a contradiction with Lemma 1.

Assume $X_n \not\subseteq E_n$ for all $n \geq n_0$. Let also, a finite sequence $x_n \in X_n$ is defined such that

$$\Gamma_{x_n} \cap (\Omega \setminus E_n) \neq \emptyset.$$

Then from $l(x_n) \geq N(\frac{1}{2n}, 2^{-n})$ the inequality

$$\left| \frac{1}{l(x_n)} \sum_{i=1}^{l(x_n)} (x_n)_i - \theta \right| < \frac{1}{2n}$$

follows. By (6) we obtain $|\theta_n - \theta| < \frac{1}{n}$. This means that the real number θ is computable. Theorem is proved. \triangle

Let Q be a computable probability distribution on θ s (i.e., on the set Ω). Then the Bayesian mixture with respect to the prior Q

$$P(x) = \int P_\theta(x) dQ(\theta)$$

is also computable probability distribution.

Recall that R_Q is the set of all infinite sequences Martin-Löf random with respect to a computable probability measure Q . Obviously, $P(\cup_{\theta \in R_Q} I_\theta) = 1$, and then $\bar{M}(\cup_{\theta \in R_Q} I_\theta) > 0$. Moreover, it follows from Corollary 4 of Vovk and V'yugin [11]

Theorem 2 *For any computable measure Q , a sequence ω is random with respect to the Bayesian mixture P if and only if ω is random with respect to a measure P_θ for some θ random with respect to the measure Q ; in other words,*

$$R_P = \cup_{\theta \in R_Q} I_\theta.$$

Notice that each computable θ is Martin-Löf random with respect to the computable probability distribution concentrated on this sequence.

4. Randomness with respect to non-random parameters

We show in this section that the Bayesian approach is insufficient to cover all possible “meaningful” cases: a probabilistic machine can be constructed, which with probability close to one outputs a random θ -Bernoulli sequence, where the parameter θ is not random with respect to each computable probability distribution.

Let $\mathcal{P}(\Omega)$ be the set of all computable probability measures on Ω and let

$$\mathcal{S} = \cup_{P \in \mathcal{P}(\Omega)} R_P$$

be the set of all sequences Martin-Löf random with respect to computable probability measures. We call these sequences - *stochastic*. Let \mathcal{S}^c be a complement of \mathcal{S} - the set of *non-stochastic* sequences.

An infinite binary sequence α is Turing reducible to an infinite binary sequence β if $\alpha = F(\beta)$ for some computable operation F ; we denote this $\alpha \leq_T \beta$. Two infinite sequences α and β are Turing equivalent if $\alpha \leq_T \beta$ and $\beta \leq_T \alpha$. Let

$$Cl(\mathcal{S}) = \{\alpha : \exists \beta (\beta \in \mathcal{S} \& \beta \leq_T \alpha)\}. \quad (10)$$

The complement of the set (10), $Cl(\mathcal{S})^c = \Omega \setminus Cl(\mathcal{S})$, consists of sequences non-random with respect to all computable probability distributions, i.e., $Cl(\mathcal{S})^c \subseteq \mathcal{S}^c$; moreover, it consists of sequences which can not be Turing equivalent to stochastic sequences. Also, no stochastic sequence can be Turing reducible to a sequence from $Cl(\mathcal{S})^c$.

V'yugin [12], [13] proved that $\bar{M}(Cl(\mathcal{S})^c) > 0$.

Theorem 3 *For any ϵ , $0 < \epsilon < 1$, a lower semicomputable semimeasure Q exists such that $\bar{Q}(E_Q) > 1 - \epsilon$ and $E_Q \subseteq Cl(\mathcal{S})^c$.*

For completeness of presentation we give in Appendix A a new simplified proof of this theorem.

We show that this result can be extended on parameters of the Bernoulli family.

Theorem 4 *Let I_θ be the set of all θ -Bernoulli sequences. Then*

$$\bar{M}(\cup_{\theta \in Cl(\mathcal{S})^c} I_\theta) > 0.$$

In terms of probabilistic computers, for any ϵ , $0 < \epsilon < 1$, a probabilistic machine (L, F) can be constructed, which with probability $\geq 1 - \epsilon$ generates an θ -Bernoulli sequence, where $\theta \in Cl(\mathcal{S})^c$ (i.e., θ is nonstochastic).

Proof. For any $\epsilon > 0$, $0 < \epsilon < 1$, we define a lower semicomputable semimeasure P such that

$$\bar{P}(\cup_{\theta \in Cl(\mathcal{S})^c} I_\theta) > 1 - \epsilon.$$

The proof of the theorem is based on Theorem 3.

Let Q be the semimeasure defined in this theorem. For any $\omega \notin E_Q$ we have $Q(\omega^n) = 0$ for all sufficiently large n . For the measure

$$R^-(x) = \int B_\theta(x) d\bar{Q}(\theta), \quad (11)$$

where B_θ is the Bernoulli measure, we have $R^-(\Omega) > 1 - \epsilon$ by Theorem 3, and $R^-(\cup_{\theta \in Cl(\mathcal{S})} I_\theta) = 0$.

Unfortunately, we can not conclude that $c\bar{M} \geq R^-$ for some constant c , since the measure R^- is not represented in the form $R^- = \bar{P}$ for some lower semicomputable semimeasure P . To overcome this problem, we consider some semicomputable approximation of this measure.

For any finite binary sequences α and x , let $B_\alpha^-(x) = (\theta^-)^K (1 - \theta^+)^{N-K}$, where N is the length of x and K is the number of ones in it, θ^- is the left side of the subinterval corresponding to the sequence α and θ^+ is its right side. By definition $B_\alpha^-(x) \leq B_\theta(x)$ for all $\theta^- \leq \theta \leq \theta^+$.

Let ϵ be a rational number. Let $Q^s(x)$ be equal to the maximal rational number $r < Q(x)$ computed in s steps of enumeration of $Q(x)$ from below. Using Theorem 3, we can define for $n = 1, 2, \dots$ and for each x of length n a computable sequence of positive integer numbers $s_x \geq n$ and a sequence of finite binary sequences $\alpha_{x,1}, \alpha_{x,2}, \dots, \alpha_{x,k_x}$ of length $\geq n$ such that the function $P(x)$ defined by

$$P(x) = \sum_{i=1}^{k_x} B_{\alpha_{x,i}}^-(x) Q^{s_x}(\alpha_{x,i}) \quad (12)$$

is a semimeasure, i.e., such that condition (1) holds for all x , and such that

$$\sum_{l(x)=n} P(x) > 1 - \epsilon \quad (13)$$

holds for all n . These sequences exist, since the limit function R^- defined by (11) is a measure satisfying $R^-(\Omega) > 1 - \epsilon$.

By definition the semimeasure $P(x)$ is lower semicomputable. Then $cM(x) \geq P(x)$ holds for all $x \in \Xi$, where c is a positive constant.

To prove that $\bar{P}(\Omega \setminus \cup_\theta I_\theta) = 0$ we consider some probability measure $Q^+ \geq Q$. Since (1) holds, it is possible to define some noncomputable measure Q^+ satisfying these properties in many different ways. Define the mixture of the Bernoulli measures with respect to Q^+

$$R^+(x) = \int B_\theta(x) dQ^+(\theta). \quad (14)$$

By definition $R^+(\Omega \setminus \cup_\theta I_\theta) = 0$. Using definitions (12) and (14), it can be easily proved that $\bar{P} \leq R^+$. Then $\bar{P}(\Omega \setminus \cup_\theta I_\theta) = 0$. By Theorem 3 $Cl(\mathcal{S}) \subseteq \Omega \setminus E_Q$, and then $\bar{Q}(Cl(\mathcal{S})) = 0$. By (12) we have $\bar{P}(\cup_{\theta \in Cl(\mathcal{S})} I_\theta) = 0$. By (13) we have $\bar{P}(\Omega) > 1 - \epsilon$. Then $\bar{P}(\cup_{\theta \in Cl(\mathcal{S})^c} I_\theta) > 1 - \epsilon$. Therefore, $\bar{M}(\cup_{\theta \in Cl(\mathcal{S})^c} I_\theta) > 0$. \triangle

Appendix A. Proof of Theorem 3

Recall that E_Q is the support set of a semimeasure Q . In that follows we define a semicomputable semimeasure Q such that

- 1) $\bar{Q}(E_Q) > 0$;
- 2) for each $\omega \in E_Q$ and for each computable operation F such that $F(\omega)$ is infinite, the sequence $F(\omega)$ is not Martin-Löf random with respect to the uniform probability measure L on Ω .

By Theorem 4.2 from [15] for each computable measure P on Ω , there exist two computable operations F and G such that

- 3) $F(\omega) \in \Omega$ for each ω random with respect to L , and $G(F(\omega)) = \omega$;
- 4) for each sequence ω random with respect to P (and such that $P\{\omega\} = 0$), the sequence $G(\omega)$ is random with respect to L .

By 1)-4) each sequence $\omega \in E_Q$ can not be Martin-Löf random with respect to any computable probability measure P .

We will construct a semicomputable semimeasure Q as a some sort of network flow. We define an infinite network on the base of the infinite binary tree. This network has no sink; the top of the tree (empty sequence) is the source.

Each $x \in \Xi$ defines two edges $(x, x0)$ and $(x, x1)$ of length one. In the construction below we will add to the network extra edges (x, y) of length > 1 , where $x, y \in \Xi$, $x \subseteq y$ and $y \neq x0, x1$. By the length of the edge (x, y) we mean the number $l(y) - l(x)$. For any edge $\sigma = (x, y)$ we denote by $st(\sigma) = x$ its starting vertex and by $ter(\sigma) = y$ its terminal vertex. A computable function $q(\sigma)$ defined on all edges of length one and on all extra edges and taking rational values is called *a network* if for all $x \in \Xi$

$$\sum_{\sigma: st(\sigma)=x} q(\sigma) \leq 1.$$

Let G be the set of all extra edges of the network q (it is a part of the domain of q). By *q-flow* we mean the minimal semimeasure P such that $P \geq R$, where the function R is defined by the following recursive equations

$$\begin{aligned} R(\lambda) &= 1; \\ R(y) &= \sum_{\sigma: ter(\sigma)=y} q(\sigma)R(st(\sigma)) \end{aligned} \tag{A.1}$$

for $y \neq \lambda$. It is easy to see that this semimeasure P is lower semicomputable if q is computable.

A network q is called *elementary* if the set of extra edges is finite and $q(\sigma) = 1/2$ for almost all edges of unit length. For any network q , we define the *network flow delay* function (*q-delay* function)

$$d(x) = 1 - q(x, x0) - q(x, x1).$$

The construction below works with all programs i computing the operations $F_i(x)$.² We define some function $p(n)$ such that for each positive integer number m we have $p(n) = m$

² The existence of the effectively computable sequence $\{F_i\}$ such that for each computable operation F , $F = F_i$ for some i is proved in [9].

for infinitely many n . For example, we can define $p(\langle m, k \rangle) = m$ and $p'(\langle m, k \rangle) = k$ for all m and k , where $\langle m, k \rangle$ is some computable one-to-one enumeration of all pairs of nonnegative integer numbers. Then for each step n we compute $\langle i, s \rangle = p(n)$, where i is a program and s is a number (we call s number of a session); so, $i = p(p(n))$ and $s = p'(p(n))$.

Let a program i , a number s , finite binary sequences x and y , an elementary network q , and a nonnegative integer number n be given. Define $B(\langle i, s \rangle, x, y, q, n)$ be *true* if the following conditions hold

- (i) $l(y) = n$, $x \subseteq y$,
- (ii) $d(y^k) < 1$ for all k , $1 \leq k \leq n$, where d is the q -delay function and $y^k = y_1 \dots y_k$;
- (iii) $l(F_i(y)) > \langle x, s \rangle$.

Let $B(\langle i, s \rangle, x, y, q, n)$ be *false*, otherwise. Define

$$\beta(x, q, n) = \min\{y : p(l(y)) = p(l(x)), B(\langle p(p(l(x))), p'(p(l(x))), x, y, q, n) \}$$

Here $p(p(l(x)))$ is a program and $p'(p(l(x)))$ is a number of session; \min is considered for lexicographical ordering of strings; we suppose that $\min \emptyset$ is undefined.

Lemma 2 *For each computable operation F_i and for each finite sequence x such that $F(\omega) \in \Omega$ for some infinite extension ω of x (i.e., $x \subseteq \omega$), $\beta(x, q, n)$ is defined for all sufficiently large n such that $p(p(n)) = i$.*

Proof. The needed sequence y exists for all sufficiently large n , since $l(F_i(\omega^n)) > \langle x, s \rangle$ holds for all sufficiently large n , $p(n) = \langle i, s \rangle$. \triangle

The goal of the construction below is the following. Each extra edge σ will be assigned to some task number $I = \langle i, s \rangle$ such that $p(l(st(\sigma))) = p(l(ter(\sigma))) = I$. The goal of the task I is to define a finite set of extra edges σ such that for each infinite binary sequence ω one of the following conditions hold: either ω contains some extra edge as a subword, or the network flow delay function d equals 1 on some initial fragment of ω . For each extra edge σ added to the network q , $B(I, st(\sigma), ter(\sigma), q^{n-1}, n)$ is true; it is false, otherwise. Lemma 5 shows that $\bar{Q}(E_Q) > 1 - \epsilon$, where Q is the q -flow and E_Q is its support set.

Construction. Let $\rho(n) = (n + n_0)^2$ for some sufficiently large n_0 (the value n_0 will be specified below in the proof of Lemma 5).

Using the mathematical induction by n , we define a sequence q^n of elementary networks. Put $q^0(\sigma) = 1/2$ for all edges σ of length one.

Assume $n > 0$ and a network q^{n-1} is defined. Let d^{n-1} be the q^{n-1} -delay function and let G^{n-1} be the set of all extra edges. We suppose also that $l(ter(\sigma)) < n$ for all $\sigma \in G^{n-1}$.

Let us define a network q^n . At first, we define a network flow delay function d^n and a set G^n .

Let $w(I, q^{n-1})$ be equal to the minimal m such that $p(m) = I$ and $m > l(ter(\sigma))$ for each extra edge $\sigma \in G^{n-1}$ such that $p(l(st(\sigma))) < I$.

The inequality $w(I, q^m) \neq w(I, q^{m-1})$ can be induced by some task $J < I$ that adds an extra edge $\sigma = (x, y)$ such that $l(y) > w(I, q^{m-1})$ and $p(l(x)) = p(l(y)) = J$. Lemma 3 (below) will show that this can happen only at finitely many steps of the construction.

The construction can be split up into three cases.

Case 1. $w(p(n), q^{n-1}) = n$ (the goal of this part is to start a new task $I = p(n)$ or to restart the existing task $I = p(n)$ if it was destroyed by some task $J < I$ at some preceding step).

Put $d^n(y) = 1/\rho(n)$ for $l(y) = n$ and define $d^n(y) = d^{n-1}(y)$ for all other y . Put also $G^n = G^{n-1}$.

Case 2. $w(p(n), q^{n-1}) < n$ (the goal of this part is to process the task $I = p(n)$).

Let C_n be the set of all x such that $w(I, q^{n-1}) \leq l(x) < n$, $0 < d^{n-1}(x) < 1$, the function $\beta(x, q^{n-1}, n)$ is defined³ and there is no extra edge $\sigma \in G^{n-1}$ such that $st(\sigma) = x$.

In this case for each $x \in C_n$ define $d^n(\beta(x, q^{n-1}, n)) = 0$, and for all other y of length n such that $x \subseteq y$ define

$$d^n(y) = d^{n-1}(x)/(1 - d^{n-1}(x)).$$

Define $d^n(y) = d^{n-1}(y)$ for all other y . We add an extra edge to G^{n-1} , namely, define

$$G^n = G^{n-1} \cup \{(x, \beta(x, q^{n-1}, n)) : x \in C_n\}.$$

We say that the task $I = p(n)$ adds the extra edge $(x, \beta(x, q^{n-1}, n))$ to the network and that all existing tasks $J > I$ are destroyed by the task I .

After Case 1 and Case 2, define for each edge σ of unit length

$$q^n(\sigma) = \frac{1}{2}(1 - d^n(st(\sigma)))$$

and $q^n(\sigma) = d^n(st(\sigma))$ for each extra edge $\sigma \in G^n$.

Case 3. Cases 1 and 2 do not hold.

Define $d^n = d^{n-1}$, $q^n = q^{n-1}$, $G^n = G^{n-1}$.

Using this construction, we define the network $q = \lim_{n \rightarrow \infty} q^n$, the network flow delay function $d = \lim_{n \rightarrow \infty} d^n$, and the set of extra edges $G = \bigcup_n G^n$.

The functions q and d are computable and the set G is recursive by their definitions. Let Q denote the q -flow.

The following lemma shows that any task can add new extra edges only at finite number of steps.

Let $G(I)$ be the set of all extra edges added by the task I , $w(I, q) = \lim_{n \rightarrow \infty} w(I, q^n)$.

Lemma 3 *The set $G(I)$ is finite and $w(I, q) < \infty$ for all I .*

Proof. Note that if $G(J)$ is finite for all $J < I$ then $w(I, q) < \infty$. Then we must prove that the set $G(I)$ is finite for all I . Suppose that the opposite assertion holds. Let I be the minimal number such that $G(I)$ is infinite. By choice of I the sets $G(J)$ for all $J < I$ are finite. Then $w(I, q) < \infty$.

By definition if $d(\omega^m) \neq 0$ then $p_m = 1/d(\omega^m)$ is a positive integer number. Besides, if $(\omega^n, y), (\omega^m, y') \in G(I)$, where $n < m$ and $l(y) = m$, then $p_n > p_m$. Hence, for each $\omega \in \Omega$ a maximal m exists such that $(\omega^m, y) \in G(I)$ for some y or no such extra edge exists. In the latter case put $m = w(I, q)$. Define $u(\omega) = 1/d(\omega^m)$.

By the construction the integer valued function $u(\omega)$ is constant on the interval Γ_{ω^m} . Hence, it is continuous in the topology generated by such intervals. Since Ω is compact in this topology, $u(\omega)$ is bounded. Then for some m' , $u(\omega) = u(\omega^{m'})$ for all ω . By the construction if any extra edge of I th type was added to $G(I)$ at some step then $d(y) > d(x)$ holds for some new pair (x, y) such that $x \subseteq y$. This is a contradiction if $G(I)$ is infinite. \triangle

³ In particular, $p(l(x)) = I$ and $l(\beta(x, q^{n-1}, n)) = n$.

An infinite sequence $\alpha \in \Omega$ is called an *I-extension* of a finite sequence x if $x \subseteq \alpha$ and $B(I, x, \alpha^n, n)$ is true for almost all n .

A sequence $\alpha \in \Omega$ is called *I-closed* if $d(\alpha^n) = 1$ for some n such that $p(n) = I$, where d is the q -delay function. Note that if $\sigma \in G(I)$ is some extra edge then $B(I, st(\sigma), ter(\sigma), n)$ is true, where $n = l(ter(\sigma))$.

Lemma 4 *Assume for each initial fragment ω^n of an infinite sequence ω some I-extension exists. Then either the sequence ω will be I-closed in the process of the construction or ω contains an extra edge of Ith type (i.e. such that $ter(\sigma) \subseteq \omega$ for some $\sigma \in G(I)$).*

Proof. Assume a sequence ω is not I-closed. By Lemma 3 the maximal m exists such that $p(m) = I$ and $d(\omega^m) > 0$. Since the sequence ω^m has an I-extension and $d(\omega^k) < 1$ for all k , by Case 2 of the construction a new extra edge (ω^m, y) of Ith type must be added to the binary tree. By the construction $d(y) = 0$ and $d(z) \neq 0$ for all z such that $\omega^m \subseteq z$, $l(z) = l(y)$, and $z \neq y$. By the choice of m we have $y \subseteq \omega$. \triangle

Obviously, $Q(y) = 0$ if and only if $q(\sigma) = 0$ for some edge σ of unit length located on y (this edge satisfies $ter(\sigma) \subseteq y$ and $d(st(\sigma)) = 1$). Then the relation $Q(y) = 0$ is recursive and $E_Q = \Omega \setminus \bigcup_{d(x)=1} \Gamma_x$.

Lemma 5 *It holds $\bar{Q}(E_Q) > 1 - \epsilon$.*

Proof. We bound $\bar{Q}(\Omega)$ from below. For any n , let q^n be the network defined at step n , R^n be defined by (A.1), and d^n be the corresponding q^n -delay function. If $w(p(n), q^{n-1}) = n$ (i.e., Case 1 holds at step n) then

$$\sum_{l(u)=n} d^n(u) R^n(u) = (n + n_0)^{-2} \sum R^n(u) \leq (n + n_0)^{-2}. \quad (\text{A.2})$$

Assume Case 2 holds at the step n and $x \in C_n$ such that $(x, y) \in G$ for some y , $l(y) = n$. Since by the construction $d^n(y) = 0$,

$$\sum_{l(z)=n, x \subseteq z} d^n(z) R^n(z) \leq \frac{d^{n-1}(x)}{(1 - d^{n-1}(x))} \sum_{l(z)=n, x \subseteq z, z \neq y} R^n(z). \quad (\text{A.3})$$

We have

$$\sum_{l(z)=n, x \subseteq z, z \neq y} R^{n-1}(z) \leq (1 - d^{n-1}(x)) R^{n-1}(x). \quad (\text{A.4})$$

By the construction $R^n(z) = R^{n-1}(z)$ for z such that $l(z) = n$, $x \subseteq z$, $z \neq y$. Then

$$\sum_{l(z)=n, x \subseteq z} d^n(z) R^n(z) \leq d^{n-1}(x) R^{n-1}(x). \quad (\text{A.5})$$

By definition $\sum (n + n_0)^{-2} \leq \epsilon$. After that, using (A.2) and (A.5) we can prove by the mathematical induction on n that

$$\bar{Q}(\Omega) = \inf_n \sum_{l(u)=n} Q(u) \geq \inf_n \sum_{l(u)=n} R(u) \geq 1 - \epsilon.$$

Lemma is proved. \triangle

Lemma 6 *For any infinite sequence $\omega \in E_Q$ and for any computable operation F if the sequence $F(\omega)$ is infinite then it is not Martin-Löf random with respect to the uniform probability distribution.*

Proof. Assume that ω is an infinite sequence and F is a computable operation such that $F(\omega)$ is infinite. Then $F_i = F$ for some i . Define

$$U_s = \cup \{ \Gamma_{\beta(x, q^{n-1}, n)} : x \in C_n, p(n) = \langle i, s \rangle \},$$

where C_n is the set from Case 2 of the construction. By definition

$$L(U_s) = \sum_{x \in C_n} 2^{-\langle x, s \rangle} \leq 2^{-cs}$$

for some positive constant c , and $F_i(\omega) \in \cap_s U_s$. Therefore, the sequence $F(\omega)$ is not Martin-Löf random. Lemma 6 and Theorem 3 are proved. \triangle
